11 Dendritic Integration

Dendrites are very long in terms of the electronic decay length. We thus might consider how dendrites compensate for the loss. One way is to generate spikes in the dendrites as a means of faithfully communicating dendritic signals from the distal ends. These issues were first addressed in hippocampal neurons by Spenser and Kandel back in 1961, whose data was consistent with dendritic spiking. While it has been known for quite some time that the dendrites of DRG cells produce spikes, a good twenty years went by until dendritic spiking was directly observed in neurons local to the mammalian brain. Recent work on hippocampal cells by the Hausser and Schiller groups shows that these spikes can substantially lower the threshold for distal input to affect spiking. Another way is to increase the strength of the synaptic input as one get’s further away from the soma. For modest losses, this is seen in the data of Magee. However, the signal still decays with distance from the soma even though there is a tendency for distal synapses to have higher currents. This drop-off is obviated by active currents, which we shall discuss in the most possible generic means.

11.1 Active currents for dendritic gain

Gain can result in amplification without a regenerative events, e.g., without a bistable potential like we talked about on the first day, in which spiking is a bistable event. The same channels are often involved in the two processes, except that for gain alone the density may be much lower, i.e., a critical current and thus a critical density must be reached for a regenerative event. Gain is usually associated with channels that are activated (or inactivated) near the resting potential of a neuron, which is typically in the range -70 to -50 mV. The two iontrophoretic gain mechanism are

- The turning on of a current that has a positive reversal potentials, such as the noninactivating or persistent \(Na^+\)-current \((V_{th} \approx -50mV)\) or the low-threshold (T- or transient-type) calcium current \((V_{th} \approx -40mV)\).
- The turning off of a current that has a negative reversal current, such as the inward rectifier potassium channel \((V_{th} \approx -60mV)\).

Without loss of generality, we consider the circuit equations for a cell with a leak current and a voltage activated persistent \(Na^+\) current. The leak current includes all the linear conductances and potentials, i.e., \(V_{Leak}\) and \(G_{Leak}\). The \(Na^+\) current is assumed to be of the form \(I_{Na} = G_{Na}P(V)[V - V_{Na}]\), where \(P(V)\) is a Boltzman activation curve of the form

\[
P(V) = \frac{1}{1 + e^{-z(V - V_{th})/k_B T}} \tag{11.11}
\]
The circuit equation for our model is

\[
C \frac{dV}{dt} = G_L[V - V_{\text{leak}}] + G_{Na}P(V)[V - V_{Na}] + I_{\text{synapse}} \tag{11.12}
\]

At steady state, such as when the cell is at its’ resting potential with no synaptic currents, \(dV/dt = 0\) and the steady state potential, denoted \(V^{ss}\), is found by solving the transcendental equation

\[
0 = G_L[V^{ss} - V_{\text{leak}}] + \frac{G_{Na}[V^{ss} - V_{Na}]}{1 + e^{-ze(V^{ss} - V_{th})/k_BT}}. \tag{11.13}
\]

For \(V^{ss} << V_{th}\), clearly \(V^{ss} \simeq V_{\text{leak}}\).

We can linearize the response for voltage changes around \(V^{ss}\) in the presence of a synaptic current \(-\delta I\). We denote \(\delta v \equiv V - V^{ss}\), so that

\[
C \frac{d(\delta V)}{dt} = \left[G_L \left|_{V=V^{ss}} \right. \frac{d[V - V_{\text{leak}}]}{dV} \delta u + G_{Na} \left|_{V=V^{ss}} \right. \frac{d(P(V)[V - V_{Na}])}{dV} \right] \delta v - \delta I. \tag{11.14}
\]

Noting that

\[
\frac{dP(V)}{dV} = \frac{ze}{k_BT} \frac{e^{-ze(V-V_{th})/k_BT}}{(1 + e^{-ze(V-V_{th})/k_BT})^2} = \frac{ze}{k_BT} P(V)[1 - P(V)] \tag{11.15}
\]

we have

\[
C \frac{d(\delta v)}{dt} = \left[G_L + G_{Na} \left(1 + [1 - P(V^{ss})] \frac{ze(V^{ss} - V_{Na})}{k_BT} \right) P(V^{ss}) \right] \delta v - \delta I. \tag{11.16}
\]

and at the new steady state

\[
\delta v = \frac{\delta I}{G_L + G_{Na} \left(1 - [1 - P(V^{ss})] \frac{ze(V_{Na} - V^{ss})}{k_BT} \right) P(V^{ss})} \tag{11.17}
\]

The key is the term that multiples \(G_{Na}\). If it is greater than zero the sodium conductance leads to a larger overall conductance and the cell is less sensitive to its inputs. On the other hand, if the term is less than zero, the overall conductance of the cell has gone down and a given input current will lead to a larger voltage change. This constitutes gain. It occurs when

\[
[1 - P(V^{ss})] \frac{ze(V_{Na} - V^{ss})}{k_BT} > 1 \tag{11.18}
\]

For the case of \(V^{ss} \sim V_{th}\), we have \([1 - P(V^{ss})] \sim 1/2\) and the inequality becomes

\[
V_{Na} - V^{ss} > \frac{2k_BT}{ze}. \tag{11.19}
\]
which is expected to be true since \((V_{Na} - V^{ss}) \sim 100mV\) and \(z \approx 1\) for \(Na^+\) channels, so \(\frac{2kT}{ze} \sim 50mV\). We have gain as the channel is at the most sensitive point for increased opening with increased voltage.

For the case of \(V^{ss} \ll V_{th}\), the term \(P(V^{ss})\) that multiples \(G_{Na}\) in the denominator is small, so there is no gain, i.e., no voltage dependent slope as
\[
\delta v \xrightarrow{V^{ss} \ll V_{th}} \frac{\delta I}{G_L}.
\]

(11.20)

For the case of \(V^{ss} \gg V_{th}\) the term \(1 - P(V^{ss})\) in the denominator is close to zero, so that we again have no gain with
\[
\delta v \xrightarrow{V^{ss} \gg V_{th}} \frac{\delta I}{G_L + G_{Na}}.
\]

(11.21)

Thus we see that gain exists only for a range of potentials not too far above \(V_{th}\).

Lastly, when the negative conductance term with \(G_{Na}\) gets big, the total conductance can go negative and we have action potential generation.

11.1.1 Evidence for gain by persistent \(Na^+\) currents

Hirsch performed measurements of the post synaptic potential caused by a distal input as a function of the post-synaptic potential. Such a systematic exploration has the means to reveal an underlying gain mechanism. In particular, in the absence of gain the post synaptic potential will decreases as the cell is depolarized due to a drop in driving force, since the synaptic current is proportional to \(V - V_{Na^+}\). In practice, Hirsch observed gain that was dependent on a persistent-\(Na^+\) current.

Wessel performed measurements of the post synaptic potential caused by a distal input as a function of the post-synaptic potential. He found that the post synaptic potential increased as the steady-state voltage of the cell increased. Unlike the experiments of Hirsch, in this case the gain was caused by a turning off of a \(K^+\) channel, the inward rectifier, so named since it’s threshold for activation is close to the reversal potential. The effect of turning off the channel is seen both in the conductance and the time constant of the cell. One consequence of the gain is that the response to successive EPSP’s increases in amplitude.

11.1.2 Evidence for gain by low threshold \(Ca^{2+}\) currents

An independent mechanism for gain is localized spikes in specific dendrites. In particular, Llinas showed that the dendrites actually produce \(Ca^{2+}\)-based, as opposed to \(Na^+\)-based spikes. The issue of localization of calcium currents was first addressed in the imaging experiments of Ross, using a \(Ca^{2+}\) sensitive dye in slice. He found that selective regions of the distal dendrites could be excited, providing experimental evidence for the idea of localized activation in dendrites.
